Abstract

Evolutionary theories of economic change identify the processes of *idiosyncratic learning* by individual firms and of *market selection* as the two main drivers of the dynamics of industries. Are such processes able to account for the statistical regularities which industrial structures and dynamics display? In this work we address this question by means of a simple multi-firm model formalizing the mechanisms of learning and selection. The interplay between these two engines shapes the dynamics of entry-exit and market shares and, collectively, the productivity and the size distributions and their patterns of growth. As such, despite its simplicity, the model is able to robustly reproduce an ensemble of empirical stylised facts, including ample heterogeneity in productivity distributions, persistent market turbulence and fat-tailed distribution of growth rates.

1 Introduction

Evolutionary theories of economic change identify the processes of *idiosyncratic learning* by individual firms and of *market selection* as the two main drivers of the dynamics of industries. The interplay between these two engines shapes the dynamics of entry-exit and market shares and, collectively, the productivities and size distributions, and the patterns of growth of both variables. Learning (what in the empirical literature is sometimes broadly called the *within effect*) stands for various processes of idiosyncratic innovation, imitation, and changes in techniques of production. Selection (what is usually denominated the *between effect*) is the outcome of processes of market interaction where more competitive firms gain market share at the expense of less competitive ones, some firms die, and others enter. The ensuing industrial dynamics presents some remarkable and quite robust statistical properties – “stylized facts” – which tend to hold across industries and countries, levels of aggregation and time periods (for a critical surveys, see Dosi, 2007, Doms and Bartelsman, 2000, and Syverson, 2011).

In particular, such stylized facts include:

- persistent heterogeneity in productivity and all other performance variables;
- persistent market turbulence, due to change in market shares and entry-exit processes;
- skewed size distributions;
- fat-tailed distribution of growth rates.
- scaling of the growth-variance relationship.

Different theoretical perspectives address the interpretation of one or more of such empirical regularities. One stream of analysis, which could go under the heading of *equilibrium evolution*, tries to interpret size dynamics in term of *passive* (Jovanovic (1982)) or *active* learning (Ericson and Pakes (1995)) by technically heterogeneous but “rational” firms. Another stream – from the pioneering work by Ijiri and Simon (1977) all the way to Bottazzi and Secchi (2006a) – studies the joint outcome of both learning and selection mechanisms in terms of the ensuing exploitation of new business opportunities.

A third stream, including several contributions by Metcalfe (see among others Metcalfe (1998)), focuses on the competition/selection side often represented by means of replicator dynamics whereby market shares vary as a function of the relative competitiveness or “fitness” of the different firms.

Finally, many evolutionary models try to unpack the two drivers of evolution distinguishing between some idiosyncratic processes of change in the techniques of production, on the one hand, and the dynamics of differential growth driven either by differential profitabilities and the ensuing rates of investment (such as in Nelson and Winter (1982)), or by an explicit replicator dynamics, (such in Silverberg, Dosi, et al. (1988) and in Dosi, Marsili, et al. (1995)), on the other.

In the following contribution we shall present a simple multi-firm model, formalizing the mechanisms of learning and selection. It is well placed in the evolutionary tradition but, to our knowledge, well beyond incumbent models, is able to robustly reproduce the foregoing ensemble of empirical stylised facts, including ample heterogeneity in productivity distributions, persistent market turbulence and fat-tailed distribution of growth rates.

One of the basic intuition in our whole interpretation is that both learning and competition processes entail *correlation mechanisms* which yield as such systematic departures from Gaussian stochastic processes. It is an intuition already explored by Bottazzi and Secchi (2006a) with respect to the exploitation of “business opportunities”, which we shall expand also in relation to competition processes. This is what Bottazzi (2014) calls the *bosonic nature* of firm growth, in analogy with the correlating property of elementary particles – indeed the bosons.

Systematic correlations induce non-fading (possibly amplifying) effects of intrinsic differences, or even different degrees of “luck”, across firms, both “intra-period” (however a “period” is defined) and over time.

Bottazzi and Secchi (2006a) show how such correlations generically underlie fat-tailed distributions of firm growth rates. We push the analysis further, showing that competition-driven replicators yield similar fat-tailedness properties. Moreover, by unpacking the learning and selection parts of the process, we attempt to distinguish what is *generic* across all processes and what is *specific* to particular learning-competition regimes. Finally, our model of industrial dynamics characterised by cumulative learning and competitive selection, or even just the latter (cum entry) is able to account for a few other salient empirical features of industrial change. Section 2 briefly summarizes the empirical regularities and Section 3 discusses the main theoretical models aimed at explaining some of them. Section 4 presents the model and Section 5 analyses the results.

2 Empirical stylised facts: productivity, size and growth

During the last few decades, enabled by the availability of longitudinal micro data, an increasing number of studies have identified a rich ensemble of “stylised facts” related to *productivities*, firm *sizes* and firm *growth rate* distributions. Let us consider some of them, germane to the results of the model which follows.

2.1 Productivity distribution and growth

As extensively discussed in Doms and Bartelsman (2000), Syverson (2011), Dosi (2007) and Foster et al. (2008), among many others, *productivity dispersion*, at all levels of disaggregation, is a striking and very robust phenomenon. Moreover, such heterogeneity across firms is *persistent over time*, (cf. Bartelsman and Dhrymes (1998), Dosi and Grazzi (2006) and Bottazzi, Secchi, and Tamagni (2008)), with autocorrelation coefficients in the range 0.8 – 1. An illustration is provided in Figure 1 for one 2-digit Italian sector and two 3-digit thereof. The distribution and its support are quite stable over time and so is the “pecking order” across firms, as suggested by the high autocorrelation coefficients: see Figure 2. These findings, which hold under parametric and non-parametric analyses, empirically discard any idea of firms’ revealed production process as the outcome of an exercise of optimization over a commonly shared production possibility set – which, under common relative prices, ought to yield quite similar input/output combinations. Rather *asymmetries* are impressive (notice the wide support of the distribution that goes from 1 to 5 in log terms), which tells of a history of both firm-specific learning patterns and of co-existence in the market of low and high productivity firms, with no trace of convergence (see Dosi, Grazzi, Tomasi, et al. (2012)). Even more so, asymmetries are pronounced in emerging economies (with only some reduction along the process of development): see on China, Yu et al.

(forthcoming). In that, the survival of dramatically less efficient firms hint at a structurally imperfect mechanism of market selection, which demand a theoretical interpretation. All this evidence relates to asymmetries in labour productivities but also to firm-level TFPs, notwithstanding the shakiness of the latter notion (more in Dosi, Grazzi, Marengo, et al. (2013), and Yu et al. (forthcoming)).

A less explored phenomenon related to the dynamic of productivity is the *double exponential nature* of its growth rate distributions. Extensive evidence is provided in Bottazzi, Grazzi, et al. (2005) and Dosi, Grazzi, Tomasi, et al. (2012): see Figure 3 for an illustration. The double exponential nature of growth rate in productivity does not only reveals an underlining multiplicative process that determines efficiency changes, but also suggests processes of idiosyncratic learning characterized by discrete, relatively frequent “big” events.

2.2 Size distribution

Firm size distributions are skewed. And this is an extremely robust property which, again, holds across sectors, countries and levels of aggregation. But, how skewed is “skewed”?

The *power-law nature* (Pareto or Zipf law, according to the slope of the straight line, in a log-log

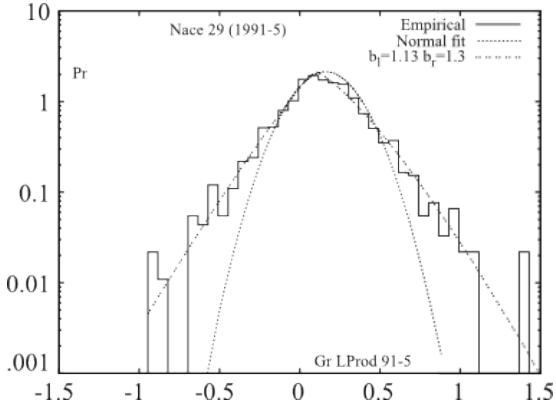

Figure 3: Tent shaped productivity growth rate. Italy, Istat Micro.3 Dataset. Source: Dosi, Grazzi, Tomasi, et al. (2012).

plot)¹ of the firm size distribution, has been investigated by many authors² since the pioneering work by Simon and Bonini (1958). This is not the place to discuss the possible generating mechanism of such distribution (an insightful discussion is in Brock (1999)). Here, just notice that on empirical grounds, size distributions across manufacturing sub-sectors differ a lot in terms of shape, fatness of the tails and even modality (Bottazzi, Cefis, Dosi, and Secchi (2007) and Dosi, Gambardella, et al. (2008)). Plausibly, technological factors, the different degree of cumulativeness in the process of innovation, the predominance of process vs. product innovation, and the features of market competition might strongly affect (fined defined) sector-specific size distributions (Marsili, 2005). Indeed, it might well be that the findings on the Zipf (Pareto) law distributions are a mere effect of aggregation as already conjectured in Dosi, Marsili, et al. (1995). Hence, what should be retained here is the skewness of the distribution rather than their precise shapes (see Figure 4 for a quite frequent shape of the upper tail).

2.3 Market turbulence

Underneath the foregoing invariances, however, there is a remarkable turbulence involving changes in market shares, entry and exit (cf. the discussion in Baldwin and Rafiquzzaman

¹See Newman, 2005 for a succinct overview.

²See Stanley, Buldyrev, et al., 1995 and Axtell, 2001 for US manufacturing data.

(1995) and Doms and Bartelsman (2000)). A good deal of such turbulence is due to “churning” of going firms, with 20% – 40% of entrants die in the first two years and only 40% – 50% survive beyond the seventh year in a given cohort.

I	Sales	Value Added
mean	0.130	0.161
stdev	0.048	0.045
min	0.0544	0.082
max	0.559	0.601

Table 1: Turbulence Index. Italy, Istat Micro.3 Dataset. Source: Grazzi et al. (2013)

An index that synthesizes the market turbulence is shown in Table 1 presenting some synthetic statistics on Italian micro data, both in terms of sales and value added market shares. The I index reads as the sum of the absolute value of market share variations

$$I = \sum_i |s_i(t) - s_i(t-1)| \quad 0 \leq I \leq 2 \quad (1)$$

2.4 Fat-tailed distributions of growth rates

A huge empirical literature testifies the emergence of the *Laplace distribution* in growth rates. A typical empirical finding is illustrated in 5. This applies across different levels of sectoral disaggregation, across countries, over different historical periods for which there are available data. This stylised fact is robust to different measures of growth, e.g., in terms of sales, value added or employment (for more details see Bottazzi, Cefis, and Dosi (2002), Bottazzi and Secchi (2006a), Bottazzi, Secchi, and Tamagni (2008) and Dosi (2007)).

Firms grow and decline by relatively lumpy jumps which cannot be accounted by the cumulation of small, “atom-less”, independent shocks. Rather “big” episodes of expansion and contraction are relatively frequent. More technically, this is revealed by fat-tailed distributions (in log terms) of growth rates. What determines such property?

In general, such fat-tailed distributions are powerful evidence of some underlying correlation mechanism. Intuitively, new plants arrive or disappear in their entirety, and, somewhat similarly, novel technological and competitive opportunities tend to arrive in “packages” of different “sizes” (i.e., economic importance).

2.5 Growth-size scaling relationships

The multiplicative process of firm growth is (roughly) uncorrelated with size, at least for not too small firms. This is what goes under the heading of the *Gibrat law*.

However, the *variance* of growth rates falls with size. How the level and growth rate of size are related to each other? Since Stanley, Amaral, et al. (1996), an extensive literature of empirical articles found a negative correlation between the variance of growth rates and size (see Sutton (2002), Lee et al. (1998)). An illustration of the phenomenon is provided in Figure 6. The underlying idea is that firms can be described as a collection of independent units, each of them characterised by an independent growth process. The bigger the firm, the higher the number of

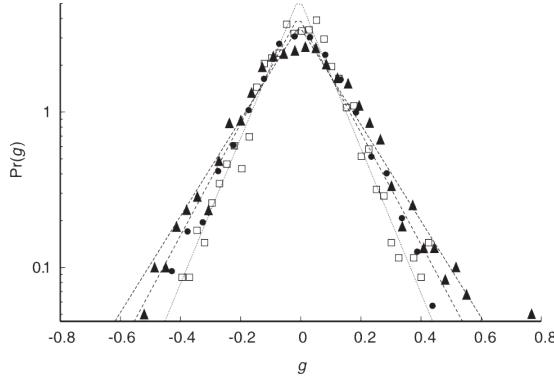

Figure 5: Tent shaped size growth rate, Italy, Istat Micro.1 Dataset. Source: Bottazzi and Secchi (2006a).

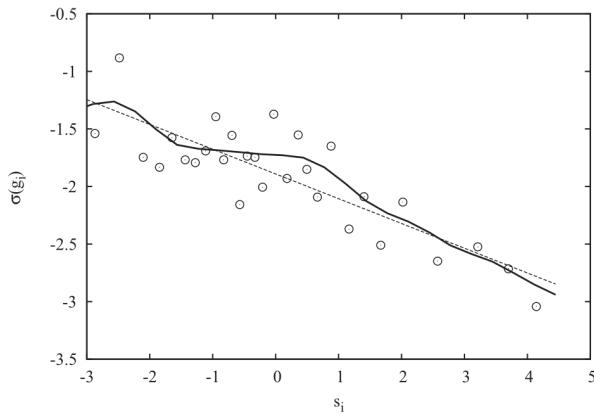

Figure 6: Variance-size relation. Elaboration on PHID, Pharmaceutical Industry Dataset. Source: Bottazzi and Secchi (2006b).

its components (“lines of business”). Hence, under an assumption of (quasi) independent growth processes for each unit, the variance of the growth rate decreases proportionally to the inverse square root of size. Bottazzi and Secchi (2006b) convincingly argue that the cause of this negative correlation is product differentiation: bigger firms tend to operate in more sub-markets which are hardly likely to be perfectly correlated. As a direct consequence, the variance of the growth rate ought to fall as the size of firms increases.

To summarize, the challenge for the theory is to account for: [i] persistent heterogeneity in productivities, [ii] skewness in size distributions, [iii] market turbulence, [iv] fat-tailed distribution of growth rates, [v] negative variance-size correlations.

How do incumbent theories fare in this respect?

3 Theoretical interpretations

Let us start from the family of “evolutionary equilibria” models, including Jovanovic (1982), Ericson and Pakes (1995), Hopenhayn (1992a), Hopenhayn (1992b) and Pakes and Ericson (1998), where there are the explicit attempts to link heterogeneity among firms, their growth and pos-

sibly survival. The evolutionary aspect lies in the idiosyncratic productivity enhancing process that leads more productive firms to expand their own capacity, or equivalently their market shares, and less productive firms to shrink their weight in the market up their death. Implicitly, there is some process of selection at work that rewards the more productive and penalize the less efficient ones. However, competitive selection never appears because rational agents “learn” their equilibrium size. These models, at a first glance distinguishable in “passive” (as Jovanovic (1982)) and “active” (as Ericson and Pakes (1995)) learning models, address issues as growth/death rates conditional on age, the dependence or not of the current size on the initial one, and the entry-exit rate in equilibrium. The “rational” attributes stem from the fact that they are characterized by profit-seeking maximizing agents over an infinite time horizon. In each period they decide the equilibrium size and whether to stay or not in the market according to their technological rational expectations. Thus, selection is never at work because it is, so to speak, “anticipated in the heads of the agents” and, as a consequence, every observed variable is an equilibrium one. Moreover, this class of models seems unable to offer any guidance on the interpretation of major stylised facts of industrial dynamics beginning with the ubiquitous fat-tailedness of growth rates.

The abandonment of strong rationality and equilibrium assumptions bears, in our view, significant fruits. Simple and “agnostic” characterizations of firm growth as a multiplicative process, such as in the seminal Ijiri and Simon (1977) work, yield insight into the explanation of observed size distributions. There, idiosyncratic shocks are modelled as an $AR(1)$ process capturing [i] the independence of growth rates from size (Gibrat Law); [ii] one-period autocorrelation of growth rates (or a single period Markov chain); and [iii] a reversion to the mean process. The growth rates are described as the sum of the independent micro-shocks. The size trajectories turn out to be random walks with drift yielding Lognormal distributions.

However, the interactiveness intrinsic to the dynamics of firm growth is still missing. And this is what different families of evolutionary and Simonesque models are meant to capture.

In such a perspective, the micro patterns of the industrial dynamics are the outcome of twin processes of *learning* and *selection* among *boundedly rational, interacting agents*. The aggregate regularities emerge as the result of the coupling of *change* and *coordination*. Models like the ones proposed in Nelson and Winter (1982), Silverberg and Lehnert (1993), Dosi, Marsili, et al. (1995), Dosi, S. Winter, et al. (2000), Bottazzi, Dosi, et al. (2001) and S. Winter et al. (2003) are somewhat different and complementary examples of the evolutionary-modelling approach. In turn, evolutionary models that address the pattern of industry evolution, grounded into learning and selection processes, can be further subdivided into three broad categories, namely [i] models which focus on the selection process (see Metcalfe (1998) for an extensive discussion); [ii] models that mainly investigate the pattern of firm growth as a process of cumulation of learning opportunities folding together learning and selection mechanism (from Ijiri and Simon (1977) to Bottazzi and Secchi (2006a)); and [iii] models which try to unpack and treat separately the two processes (e.g., Silverberg, Dosi, et al. (1988) and Dosi, Marsili, et al. (1995)).

Of particular interest for our purpose here, are those Simonesque models which parsimoniously but powerfully account for correlating mechanisms of both learning and competition, such as Bottazzi and Secchi (2006a), nesting such correlations into firm-specific increasing returns to (correlated) business opportunities. Building upon the “island” model by Ijiri and Simon (1977), they introduce the hypothesis of exploitation of such business opportunity via a Polya Urn scheme, wherein in each period “success breeds success”. It is a two-step model, where in the

first step an assignment procedure of the *fixed number* of business opportunities M is realised. In the second step, these business opportunities act as source of growth.³ The dynamics of firms growth rate is still of a *Gibrat type* but with the significant difference that the number of opportunities M are not assigned with a constant probability $1/N$, being N the number of firms, but proportionally to the number of opportunities that in *each period* the firm already has accessed, which is obviously correlated to the opportunities of all other firms (as the overall number of opportunities is given). At each time step a micro-shock attributed to a type/firm $i \in \{1, \dots, N\}$ is extracted from an urn. Once it is extracted, the ball is replaced and, additionally, a new ball of the same colour is introduced. This implies that, once one type i has been extracted, the probability of that type being re-extracted increases. This procedure is repeated M times, i.e., the number of the total business opportunities. Indeed this cumulative process is at the core of the emergence of fat-tailed distributions. Bottazzi and Secchi (2006a) demonstrated that when N and the ratio M/N increase, the limit distribution of this scheme is Laplace distributed and this occurs independently from the distribution function of the shocks. This explanation, which we share, of the observed “tent shape” of growth rates relies on the idea that big chunks of the micro-shocks M are concentrated in relatively few firms. However, a drawback of this representation is that the assignment procedure occurs within each period. Dynamic increasing returns occur in “space” (that is, cross-sectionally) but never over time (i.e., across periods). That is all firms start from sketch at the beginning of – say, a year – to seize their opportunities when the urn is open: an assumption hardly in tune with the cumulativeness over time of corporate capabilities.

Our conjecture is that synchronous cumulative processes are only one of the drivers of the apparent correlations underlying the “tents” in growth rates. Indeed, we suggest that a rather large ensemble of evolutionary processes, characterized by different forms of *idiosyncratic* (i.e., firm-specific) *learning* and *competitive interactions* yields the observed distributions of growth rates. This is the hypothesis we are going to explore in this work. Moreover we shall show an explicit account of learning and selection dynamics that is able to robustly explain *together* all the other stylised facts flagged above.

4 The model

The model is an evolutionary model microfounded upon simple behavioural rules and heuristics. The absence of any rational expectations (technological or otherwise) is intentionally pursued. Most of individual (and more so organizational) decisions and behaviours take place under conditions of environmental complexity, radical uncertainty and massively imperfect information. The microeconomics of our model fully acknowledges all that and is inscribed within the perspective of “bounded rationality”, written large (within a vast literature, see the classic March and Simon (1958), Nelson and Winter (1982), and Gigerenzer and Selten (2002)).

The three processes that take place in the simulated industry are learning, selection and entry-exit.

³A further development along similar lines with a birth process of new types of opportunities (i.e., balls of different colors) is in Marengo and Zeppini (2014).

4.1 Idiosyncratic learning processes

We build upon a simplified version of Dosi, Marsili, et al. (1995) whereby learning is represented by some multiplicative stochastic process upon firms productivities – or more generically “levels of competitiveness” – a_i of the form

$$a_i(t) = a_i(t-1)(1 + \theta_i(t)) \quad (2)$$

where the $\theta_i(t)$ are realizations of a sequence of random variables $\{\Theta_i\}_{i=1}^{N(t)}$, and $N(t)$ is the number of firms. Such dynamics is meant to capture the idiosyncratic accumulation of capabilities within each firm (see Teece et al. (1994) and Dosi, Nelson, et al. (2001)). This entails various types of process innovation – yielding higher production efficiency and plausibly lower output prices – and new and improved products. This latter dynamics is not explicitly formalized in our utterly simple model but one may think of new products as higher value added ones, thus implicitly proxied by higher value of a_i .

The process is a multiplicative random walk with drift: the multiplicative nature is well in tune with the evidence on productivity dynamics under the further assumption that if a firm draws a negative θ_i , it will stick to its previous technique (negative shocks in normal times are quite unreasonable!).

We experiment with different learning processes, whereby $\theta_i(t)$ is drawn from a set of possible alternative distributions, namely Normal, Lognormal, Poisson, Laplace and Beta. Eq. (2) models learning in our *Baseline Regime*. Further, we experiment, as one already did in Dosi, Marsili, et al. (1995), with two other more extreme regimes, named *Schumpeter Mark I* and *Schumpeter Mark II*, somewhat dramatizing the role attributed to entrants vs. incumbents by the “young Schumpeter” (Schumpeter, 1912) and the “old Schumpeter” (Schumpeter, 1947).

Under *Schumpeter Mark I*

$$\theta_i(t) = 0 \quad (3)$$

for all incumbents. Conversely, under *Schumpeter Mark II*

$$\theta_i(t) = \pi_i(t) \left(\frac{a_i(t-1)}{\sum_i a_i(t-1) s_i(t-1)} \right)^\gamma \quad (4)$$

where $\pi_i(t)$ is the same draw process as under the *Baseline Regime*. At one extreme, in the first case, incumbents do not learn after birth. Advances are only carried by new entrants. At the opposite extreme, in the latter case, incumbents do not only learn, but do it in a cumulative way so that a draw by any firm is scaled by its extant relative competitiveness. This captures what Paul David, quoting Robert Merton, called the “Matthew effect”.⁴

4.2 Market selection and birth-death processes

Competitive interactions are captured by a “quasi replicator dynamics”

$$\Delta s_i(t, t-1) = A s_i(t-1) \left(\frac{a_i(t)}{\bar{a}(t)} - 1 \right) \quad (5)$$

where

$$\bar{a}(t) = \sum_i a_i(t) s_i(t-1) \quad (6)$$

⁴“For unto every one that hath shall be given, and he shall have abundance: but from him that hath not shall be taken even that which he hath” (Matthew 25:29, King James Version).

where $s_i(t)$ is the market share of firm i which changes as a function of the ratio of the firm's productivity (or "competitiveness") to the weighted average of the industry. It is a "quasi-replicator" since a genuine replicator lives on the unit simplex. The "quasi" one may well yield negative shares, under certain parametrizations, in which case the firm is declared dead and market shares are accordingly recomputed. A is an elasticity parameter that captures the intensity of the selection exerted by the market, in terms of market share dynamics and, indirectly, of mortality of low competitiveness firms. Below, we shall study the effect of different degrees of *market selectiveness* upon industry structures and dynamics.

Finally, we assume that entry of new firms occurs proportionally to the number of incumbents present in the market

$$E(t) = \omega(t)N(t - 1) \quad (7)$$

where $E(t)$ is the number of entrants at time t , $N(t - 1)$ is the number of incumbents in the previous period and $\omega(t)$ is a random variable uniformly distributed on a finite support (which in the following, for simplicity, we assume drawn from a uniform distribution). The idea that the number of entrants is proportional to the number of incumbents is strongly corroborated empirically: see e.g., P. Geroski (1991) and P.A. Geroski (1995). However, the evidence supports also a rough proportionality between entry and exit: thus, in the simplest version of the model, we assume a constant number of firms with the number of dying firms offset by a equal number of entrants.

The productivity of entrants follows a process similar to Eq. (2) but applied to the *average productivity* of the industry, whose stochastic component $\theta_j(t)$ is again a random extraction from alternative distributions (Normal, Lognormal, Poisson, Laplace and Beta)

$$a_j(t) = (1 + \theta_j(t)) \sum_i a_i(t)s_i(t - 1) \quad (8)$$

Of course, here $\theta_j(t)$ can get negative values. Indeed, the location of the mass of the distribution – over negative or positive shocks – captures barriers to learning by the entrant or, conversely, the "advantage of newness".

4.3 Timeline of events

- There are N initial incumbent firms. At time 0 they have equal productivities and equal market shares.
- At the beginning of each period, except under Mark I Regime, firms learn according to the process specific to each regime.
- Firms acquire or lose market share, according to the replicator.
- Firms exit the market according to the rule: $s_i(t) < s_{min}$.
- The number, the competitiveness and the size of entrants are determined and market shares of incumbents are adjusted accordingly.

	Value
Number of firms (N)	150
Initial productivity	1
Initial market share ($1/N$)	0.006667
s_{min}	0.001
A	1
γ	1

$Normal(\mu, \sigma)$	(0.05, 0.8)
$Lognormal(\mu_1, \sigma_1)$	(-3.5, 1)
$Laplace(\alpha_1, \alpha_2)$	(0.01, 0.015)
Number of time steps	200
Number of MC runs	50

Table 2: Parameters and simulation setup.

5 Model properties and simulation results

Let us consider the model properties together with the simulation results which we shall present according to the empirical “stylised facts” the model is able to replicate. The model is parametrized according to Table 2 and the benchmark distribution for the extraction of the micro-shocks is a Beta distribution if not otherwise specified.

5.1 Productivity distribution

The productivity distributions obtained from the three regimes are presented in Figure 7. The normalized productivity distributions are calculated as

$$c_i(t) = \log a_i(t) - \log \sum_i a_i(t) s_i(t-1) \quad (9)$$

As already mentioned, $c_i(t)$ turns out in the real world to be rather disperse over a wide support with a persistency of such asymmetries over time. It is interesting to notice how the support of the distribution (in logs) spans between (-1, 0.5) in the Baseline Regime, shrinks in the Mark I Regime (-0.5, 0.2), and expands in the Schumpeter Mark II (-1.4, 0.8). If innovation is endogenous the support is wider and even more so if it is cumulative as under the Schumpeter Mark II regime.

The autocorrelation structure of productivities is reported in Table 3: the coefficients are well in tune with the empirical evidence.

Autocorrelation	$AR(1)$
<i>Baseline Regime</i>	0.970
<i>Schumpeter Mark I Regime</i>	0.986
<i>Schumpeter Mark II Regime</i>	0.987

Table 3: Autocorrelation coefficients in relative productivities.

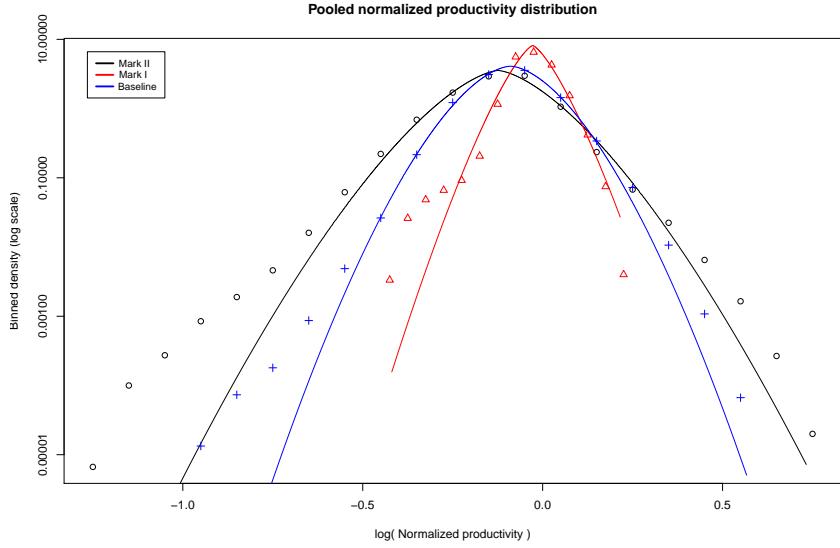

Figure 7: Log normalized productivity distribution across regimes.

5.2 Market turbulence and concentration

The dynamic of entry and exit in all scenarios drives an everlasting churning dynamics. Table 4 presents an ensemble of descriptive statistics about the number of entrants, the average age, the average productivity growth, the average size growth, the entry-exit dynamics, and the market concentration.

Interestingly, and somewhat counterintuitively, firms' life expectation is the highest under the no-incumbent learning (Schumpeter Mark I) regime (21 periods) and the lowest in the cumulative regime (4 periods). This is a robust sign of the effects of "creative destruction" when innovation is endogenous, even (indeed, especially) when learning is highly cumulative, with a galaxy of fringe firms entering and quickly dying around a "core" of successful incumbents. The three regimes show increasing degrees of turbulence, from Mark I to Mark II (see Figure 8). The reported average values are strikingly close to the empirical data shown in Table 1.

Finally, the market concentration, measured by the Herfindahl-Hirschman Index⁵ in typical simulation runs, is illustrated in Figure 9. The Mark I Regime concentration is relatively low and stable over time; conversely, in the Baseline and in the Mark II regimes, phases of high and low concentration alternate, signalling the presence of endogenous cycles which are not related to "market power" but, rather, to the path-dependent dynamics of innovative successes and ensuing differential competitiveness.

5.3 Size distribution

Regarding firm size distribution, proxied by the market shares s_i , Figure 10 shows the rank-size plot (in logs). If the size distribution follows a power law, being r_i the rank of firm i , then

$$s_i r_i^\tau = C \quad (10)$$

linearising we have

$$\log r_i = \alpha + \tau \log s_i \quad (11)$$

⁵ $H(t) = \sum_i s_i^2(t)$ $0 < H \leq 1$

Baseline Regime	Average	Min	Max	S.E.
Number of entrants	12.14 (0.792)	0 (0.000)	15.64 (1.198)	2.974 (0.479)
Average age	8.376 (0.286)	1 (0.000)	11.02 (0.383)	1.067 (0.171)
Average productivity growth	0.046 (0.0005)	0.045 (0.0004)	0.051 (0.0008)	0.001 (0.0002)

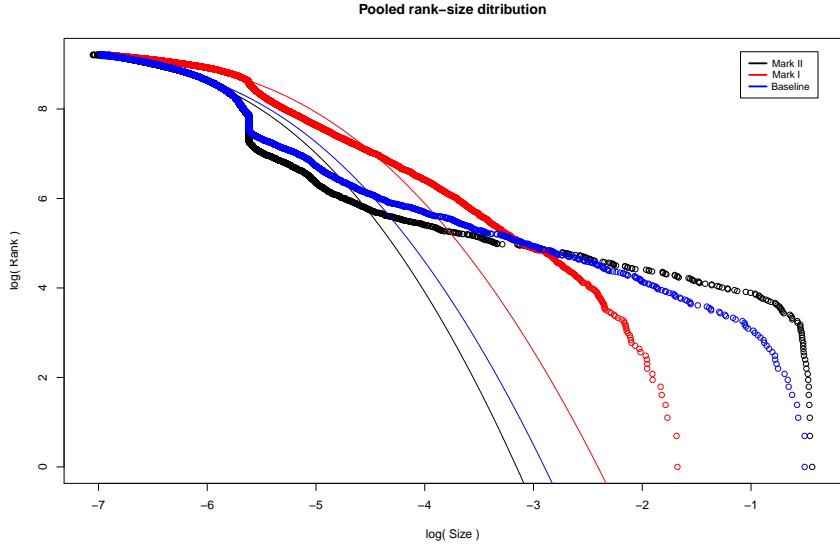

Figure 10: Log rank-size distribution across regimes.

with τ , the slope parameter: under the Zipf law (which is a restriction of the Pareto scaling) τ is equal to one. Recall from Section 2 above that the empirical size distributions, at relatively disaggregated levels, are far from any power law. And so are generally our results, with a slope clearly different from one. However, beyond some cut-off point sizes appear to be rather skewed across all the three regimes (compared with the Lognormal fit which we added as a benchmark). In case of the Schumpeter Mark I, the cut-off point is higher than in the other two cases: a bigger fraction of firms belong to the upper tail in the Baseline and the Mark II regimes. Again, these results seem in line with the empirical evidence discussed in Section 2.2.

5.4 Firm growth

The growth rate of firm sizes is defined as

$$g_i(t) = \log s_i(t) - \log s_i(t-1) \quad (12)$$

where market shares are our proxy for size. Figure 11 shows the growth rate distributions across the three regimes. Notice the strong fat-tailed departure from any Normal distribution in all the three regimes.

In order to test for the robustness of these results, we experimented with four alternative distributions for the innovation shocks, namely Laplace, Lognormal, Normal, and Poisson. Figure 12 shows the results for the four distributions across the three regimes. The departure from (log)normality and the emergence of fat tails is rather striking, independently from the shape of the micro-shocks.

To understand how “fat” the tails are, we estimated the parameters of a symmetric Subbotin distribution, defined by the parameters m , a and b , wherein m is a location measure, a is the scale parameter capturing the central part of the distribution and b the fatness of the tails. The Subbotin distribution

$$f_S(x) = \frac{1}{2ab^{1/b}\Gamma(1/b+1)} e^{-\frac{1}{b}|\frac{x-\mu}{a}|^b} \quad (13)$$

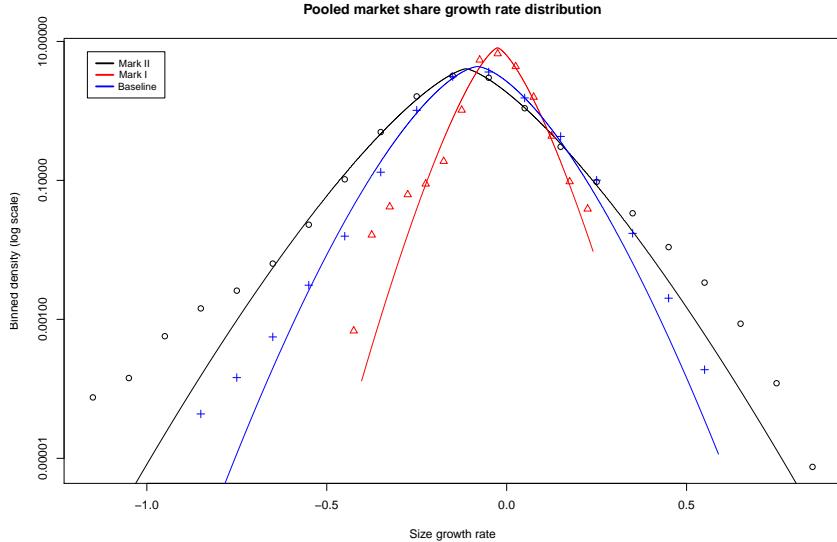

Figure 11: Growth rate distribution across regimes.

according to the value of the parameter b , can yield [i] a Normal distribution, if $b = 2$, or [ii] a Laplace distribution, if $b = 1$. Estimates of the Subbotin distribution parameters are presented in Table 5. Across the three regimes, the value of the b parameter is always significantly smaller than 2 (the Normal case).

What is the source of the tent-shaped distribution of growth rates? Start by noting that the *competitive process as such* induces ex post correlation in growth rates: the growth of the share of any one firm induces the fall of the total share of its competitors. Indeed, replicator dynamics yields a mechanism of correlation equivalent to a Polya urn mechanism.

As demonstrated by Schreiber (2001) and discussed in Pemantle (2007), *the stochastic replicator is a generalized Polya urn scheme*. According to the latter, suppose that, at each time $t \geq 0$, there is a population of firms $N(t)$ whose only attribute is the relative “fitness” (or “competitiveness” or productivity as in our case) $m_i(t) = a_i(t)/\bar{a}(t)$, $i \in \{1, \dots, N\}$. These firms can be represented in an urn with balls of colors m , being $m_i(t)$ the relative “fitness” of firm i and the market share $s_i(t)$ its outcome. At each time step t two balls (firms) are randomly extracted and get their $m_{i,j}$ compared. The firm with the higher fitness reintroduces its ball and adds another one of the same color. Along the process, being $m_i(t)$ a measure of the fitness of firm i in the population, its representation $s_i(t)$ (market share) changes proportionally to its fitness against the others $N(t) - 1$ firms/balls: the growth of firm i is proportional to its own success against all the other firms, weighted by their own representation in the population. That is, in our formulation

$$\Delta s_i(t, t-1) \simeq a_i(t)s_i(t-1) / \sum_i a_i(t)s_i(t-1) \quad (14)$$

As Schreiber (2001) and Pemantle (2007) show, local, pairwise interactions yield asymptotically to the replicator properties of the system. Indeed, the competitive dynamics induces long-range correlations across the whole population also under finite total number of new balls (“opportunities”) per period, here as well as in Bottazzi and Secchi (2006a). A tricky issue, in all Polya-type models, is the relationships between the periods over which we measure variables, say years, and the frequency of arrival of “opportunities events”. This is beyond the scope of this work. Let us

	Baseline Regime <i>b</i>	Schumpeter Mark I Regime <i>b</i>	Schumpeter Mark II Regime <i>b</i>
<i>Beta shocks</i>	1.539 (0.006)	1.397 (0.003)	1.367 (0.006)
<i>Gaussian shocks</i>	1.637 (0.005)	1.426 (0.003)	1.402 (0.007)
<i>Laplace shocks</i>	1.489 (0.007)	1.360 (0.003)	1.284 (0.007)
<i>Lognormal shocks</i>	1.467 (0.006)	1.329 (0.003)	1.327 (0.006)
<i>Poisson shocks</i>	1.327 (0.007)	0.900 (0.001)	1.231 (0.007)

Table 5: Estimation of the b parameters across regimes under different innovation shocks

just notice that sufficient to our argument is the monotonicity in the two dynamics.

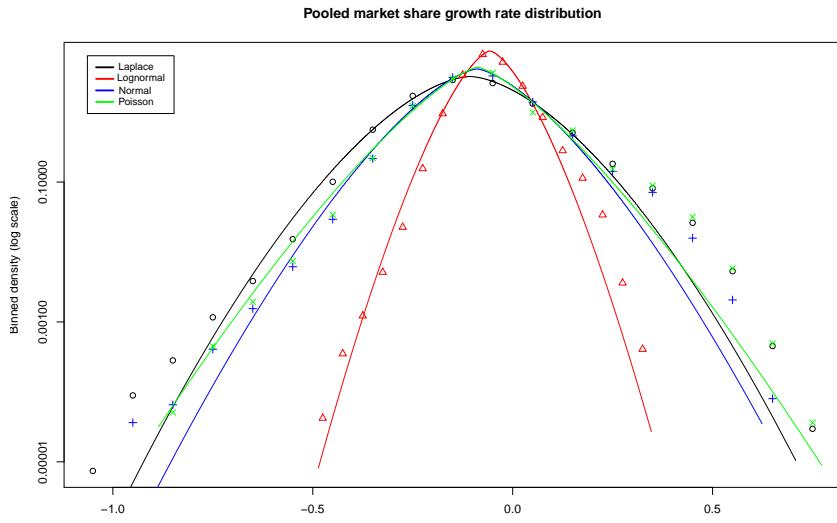

The basic intuition, our simulations show, holds *generically* across alternative shapes of micro-shocks and robustly reproduces the fat-tailed distribution of growth rates under the three learning processes. Remarkably, in the *Schumpeter Mark II* case, a strict Laplace distribution emerges.

5.5 Scaling growth-variance relationship

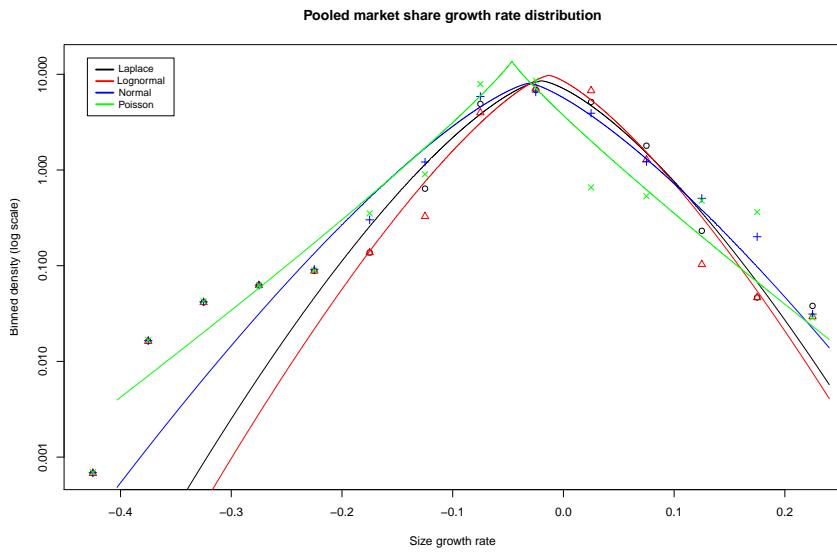

Figure 13 shows the negative correlation between the variance of growth rate and size, together with an *OLS* fit for the data

$$\sigma(g_i) = \alpha + \beta s_i \quad (15)$$

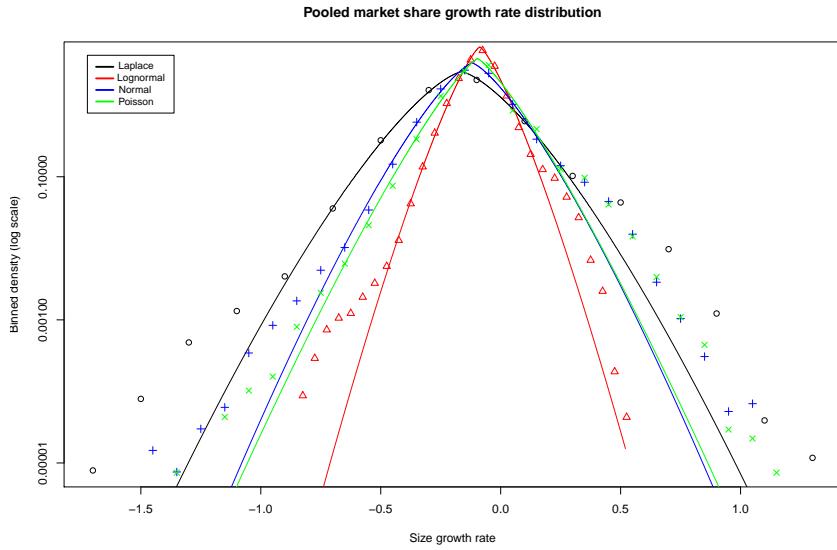

The slope coefficient β is presented in Table 6 (here the independent variable are market shares rather than sheer size, but the two, in finite markets, easily map). Across the three regimes, the negative linear correlation is always present. It is important to notice that our scaling is linear in size and not log-linear like in empirical data. However in our simple model we do not have diversification and multi-product firms. And, expectedly, we do not find any power law type scaling of the growth variance-size relationship. But, what is the source of any persistent negative relationship even if of a linear nature? A possible theoretical origin of variance scaling, as already mentioned, has been extensively discussed in Bottazzi and Secchi (2006b), and we believe that is the first order interpretation. In our model there is no possibility of a process of differentiation, but nonetheless the negative scaling holds. Why? Recalling Eq. (5), it is straightforward how the size growth rate depends on the firm relative productivity $m_i = a_i/\bar{a}$. The higher the size (share) of firm i , other things being equal, the nearer the firm is to the market weighted average, since it disproportionately contributes the average itself. It is as if size as such “bends” the selection landscape. In order to visualize this, think of the extreme of a monopolist: in this case, its own competitiveness is also the market average and, of course, the replicator dynamics impact upon growth variance is nil. At the opposite extreme, smaller firms might be by far more or less competitive than the mean but, because of their size, they have a negligible effect upon the “selection” process. Hence, their growth rates are more prone to

<i>Schumpeter Mark I Regime</i>	-0.190 (0.01)
<i>Schumpeter Mark II Regime</i>	-0.4121 (0.008)

Table 6: Estimation of the slope coefficient of linear scaling variance-growth correlation across regimes.

fluctuate. This induce the emergence of a *core-periphery* structure where bigger firms tend to have a lower variation in their growth rate while the smaller ones fuel the turbulence of market shares. Needless to say, this interpretation of the variance scaling relation does *not* contradict the diversification hypothesis. It just adds to it a scale dependence of the very yardstick of competitive selection.

5.6 Cumulativeness and selection

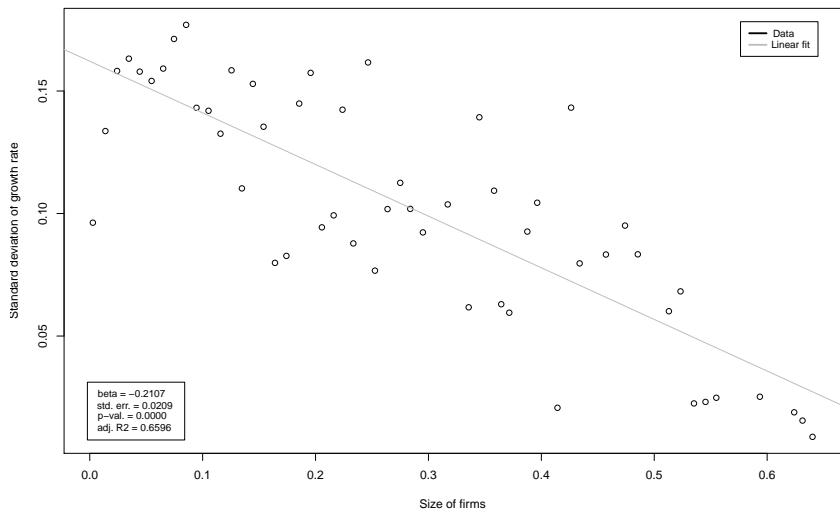

We have argued above that the very competition process robustly induces fat-tailed distributed growth rates, even in absence of learning. But of course, cumulative learning is also plausibly enhancing such fat-tailedness, and so does the increase in the “fierceness” of competition. Let us explore this conjecture in the case of the Schumpeter Mark II regime. To do this, we study the effects on the distribution of firms growth rate of the γ parameter, which captures the degree of cumulativeness in the learning process, and the A parameter, which embodies the selectivity of the market mechanism.

We start by analysing the effect of cumulativeness. As expected, the increase in the γ parameter, as shown in Figure 14, induces a more tent-shaped distribution of the growth rates, up to the point of becoming “super Laplacian”, with the estimate of b – the tail estimate of the distribution – falling below one. Notice that the estimates under such regime are those which look closer to the empirical ones, circumstantial evidence that Matthews effects are quite widespread. It is worth underlining that the causality here goes from the cumulative learning process to the selection mechanism and, then, to the dynamics of firm growth, *in absence of any contemporaneous correlation among the productivity shocks themselves*.

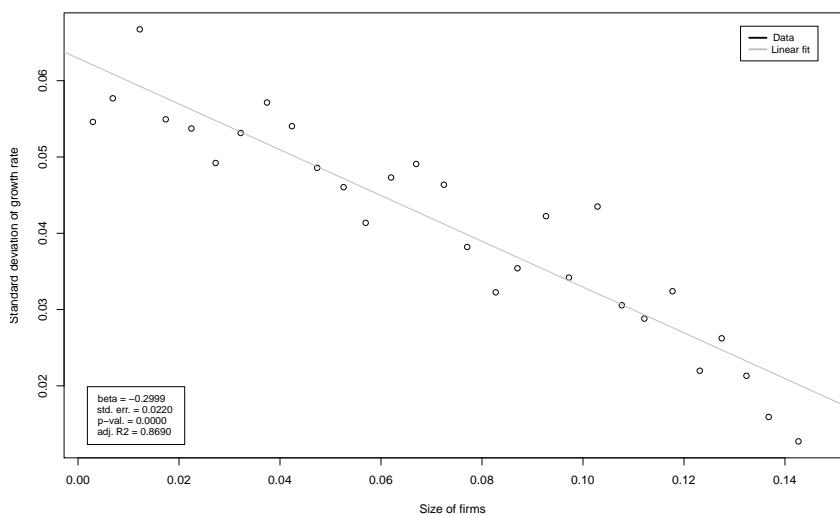

Regarding the effect of parameter A , Figure 15 illustrates the asymmetric effects of different degrees of market selectiveness. On the one side, A influences the support of the tail of surviving, negative-growth firms and, on the other, the growth of successful ones, that is, the conditions of the coexistence of both high growth firms, the “gazzellas” at the upper-right tail, and the “laggards” at the lower-left tail. This hints that the selection parameter is positively correlated to the asymmetry of the distribution.

6 Conclusions

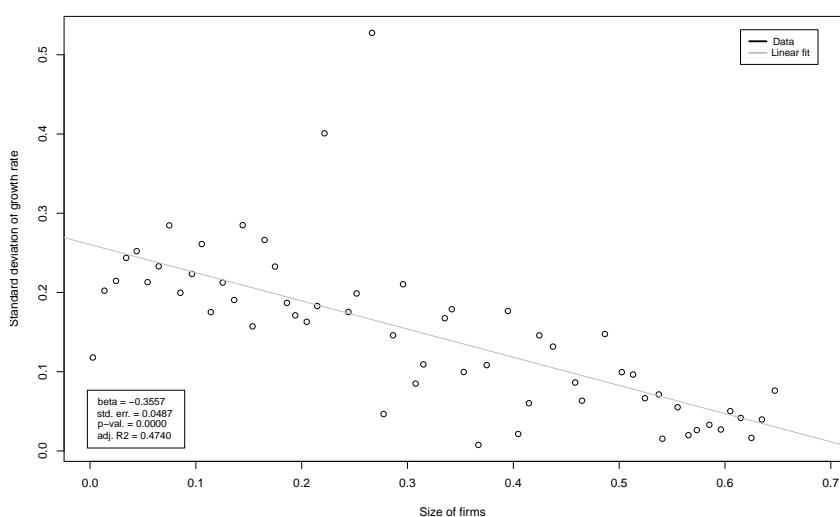

There is an ensemble of “stylised facts” on industrial dynamics which ubiquitously emerges across industries, levels of aggregation, times and countries. They include: wide and persistent asym-

metries in degrees of relative efficiency, however measured; skewed size distributions; persistent turbulence in market dynamics; negative scaling relations between firm sizes and variance in firm growth rates; and, last but not least, fat-tailed distributions of growth rates themselves. We show that all these regularities can be accounted for by a very simple evolutionary model whereby the dynamics is driven by some learning process by incumbents and entrants (or at least by entrants alone) together with some process of competitive selection. They correlate the growth (and survival) fates across firms, even in absence of correlations in the original “technological shocks” themselves. We also show that this interpretation is robust to different learning and competition regimes, including the extreme archetypes wherein incumbents do not learn at all or, other, with incumbents building success upon success.
